Title: Solid- and Grid-Sphere Current Collection in
View of the TSS-1, TSS-1R Missions Results

Abstract

Passive end-body plasma contactors have been operationally validated in space and shown to provide a simple, effective and robust means of current collection at the positive terminal of an electrodynamic tether system. A grid-sphere has been suggested as a possible end body since it potentially has distinct advantages compared to a solid sphere, including a lower neutral dynamic drag and a higher current-to-mass ratio. This paper estimates the maximum current collected by a grid-sphere taking into account its orbital motion and ion production inside the grid-sphere. We first review the data from the Tethered Satellite System (TSS-1) and the TSS-1R flights, formulate a model for current collection by a solid sphere, and suggest how to incorporate it into the grid-sphere current collection estimate. Then we calculate the potential distribution inside the grid-sphere and the potential distribution outside the solid sphere for the same system parameters. Finally we estimate the maximum current collected by a grid-sphere depending on its transparency.

Keywords: passive plasma contactors, electrodynamic tethers.

1. Introduction

There are a number of space applications for electrodynamic tether systems that require high current on the order of dozens of amperes for operation. Closure of the electric circuit of an electrodynamic tether necessarily requires an electrical connection between the tether’s positive electrode and the ambient ionospheric plasma, where the anode may take various forms. It may be a spherical solid-surface conducting end-body that has been systematically studied for the TSS missions, or it may be the positively biased portion of the tether itself as was planned for the ProSEDS flight demonstration. No matter what the geometry of the collection area might be, the collection, for example, of 10 amperes requires a large current collection surface on the order of $1000 \text{ m}^2$, because ionospheric thermal current is only about $10 \text{ mA/m}^2$. That is why there is a constant search for the most efficient and light end-body contactor.

Passive end-body contactors have been validated in space and provide a simple, effective, and robust means of current collection at the positive terminal of an electrodynamic tether system. Determination of the most effective type of contactor is primarily based on its current collection efficiency, dynamic drag, and mass. Stone and Gierow [2001], Stone et al. [2002] have proposed a grid-sphere end-body with high transparency, about 90%. They argue that such a design has distinct advantages, providing a large current collection area, low dynamic drag and high current-to-mass ratio. Their preliminary results regarding the grid-sphere performance, based on a calculation of the current collection for cylindrical and spherical bodies, suggest that it may be a simple and reliable means of developing large tether currents, unencumbered by high power requirements, hot filaments, expendables, and the complex electronics associated with existing active contactor devices.
Their analysis of current collection for a grid-sphere assumed that there is no positive charge inside the sphere and neglected the tether system orbital motion. The motion, as known from the results of the TSS-1 and TSS-1R missions, substantially increases the current collected by a solid sphere [Wright et al., 1996; Thompson et al., 1998]. We present below a calculation of the maximum current collection by a grid-sphere taking into account the orbital motion, as well as the ion production from ionization of neutrals by incoming energetic electrons inside the grid-sphere. The paper is organized as follows: Section 2 reviews the current collection of TSS-1 and the TSS-1R flights, and presents a model for solid sphere current collection; Section 3 describes the potential distribution formation inside the grid-sphere; Section 4 suggests how to incorporate the results of Sections 2 and 3 into the grid-sphere current collection studies and calculate the upper bound for this current; and Section 5 summarizes the results.

2. Model for a Solid Sphere Current Collection

One of the major goals of the TSS-1 and TSS-1R flights was to study the electron current collected by a solid-sphere subsatellite at a large positive voltage with respect to the surrounding plasma. During both flights, the subsatellite’s current collection was observed to be in excess of the values predicted by Parker and Murphy [1967] by a rough factor between 2 and 6, when the potential was between 20 – 1000 V positive with respect to the subsatellite’s surroundings. Such an outcome was very surprising in view of the large mean electron thermal speed (212 km/s for the thermal energy ~0.1 eV), compared with their relative drift speed about 8 km/s due to the satellite’s orbital motion. To explain these results, several theoretical approaches have been developed (Dobrowolny et al., 1995; Vannaroni et al., 1998; Katz et al., 1994; Laframboise, 1997; Cooke and Katz, 1998; Ma and Schunk, 1998; Singh and Leung, 1998) that focused mainly
on the TSS-1 or TSS-1R observations. In this section we present a model for solid sphere current collection based on these theoretical results and the experimental data from both TSS missions. Using this model, we will estimate the maximum current collected by a grid-sphere.

For a solid sphere contactor we assume that the region outside the sphere can be divided in two shells (Figure 1). The inner region, starting from the sphere surface, is assumed to be spherically symmetric with a Boltzmann ion distribution and one-dimensionally accelerated electrons (Laframboise and Parker, 1973; Laframboise, 1997). The outer boundary of this region, \( r_b \), is the iso-potential surface that reflects the ion flux related to satellite motion (Laframboise, 1997; Cooke and Katz, 1998) and collects a current equal to the upper-limit current found by Laframboise and Parker [1973] for two-dimensional electron acceleration. According to Laframboise and Parker [1973], this current, collected in our model at the boundary of the first region, is:

\[
\frac{I}{I_0} = \frac{1}{\sqrt{\pi}} \frac{r_b^2}{R^2} \left( \sqrt{\chi_b} + \frac{1}{2\sqrt{\chi_b}} \right)
\]

(1)

where \( R \) is the sphere radius, \( r_b \) is the boundary radius, and \( \chi_b = e\phi_b / kT \) is the normalized potential (\( \phi_b \) is the potential of the boundary, \( e \) is the elementary charge, \( T \) is the plasma temperature, and \( k \) is the Boltzmann constant). The current is normalized to \( I_0 = \pi R^2 e n_\infty \sqrt{8kT/m} \), the random electron current. Here \( n_\infty \) is the undisturbed plasma density and it is assumed in expression (1) that the current is collected only by the leading ram hemisphere. Following Cooke and Katz [1998] and Laframboise [1997], the potential at the boundary is set equal to the energy needed to reflect the ions, defined by the normal component of the ion velocity relative to the satellite and averaged over the sphere surface. So \( \chi_b = E_i / 3kT \) where \( E_i = 5eV \) is the ion kinetic energy.
To calculate the current from equation (1), the radius of the boundary, \( r_b \), that separates the regions of one- and two-dimensional acceleration should be found. To calculate \( r_b \), the Poisson equation in the region between the grid-sphere surface and the boundary has been solved

\[
\frac{1}{x^2} \frac{d}{dx} \left( x^2 \frac{d\chi}{dx} \right) = \frac{R^2}{\lambda_D^2} \left( \frac{2}{\sqrt{\pi e}} \chi \right) e^{-\frac{e^2}{R^2}}, \quad 1 \leq \frac{r}{R} \leq \frac{r_b}{R}, \quad \chi = \frac{e\Phi}{kT}, \tag{2}
\]

The electron density here corresponds to the one-dimensional acceleration case (Laframboise and Parker, 1973) with \( \chi \gg 1 \), where \( \lambda_D \) is the Debye length. At the outer boundary of this region, \( r_b \), the electron density is chosen equal to the ion density, which because of ion reflection is set at twice the undisturbed ion density (Laframboise, 1997).

To calculate the unknown radius \( r_b \) from equation (2), a third condition is needed, which could be provided by the solution in the outer domain \( r > r_b \). Instead, we simplify the problem by assuming that the boundary \( r_b \) between the regions of one- and two-dimensional acceleration can be identified as the position where the electric field abruptly drops and changes sign, indicating that further out the one-dimensional electron density distribution is not valid. As can be expected from equation (2), it is also the radius where the potential, \( \chi \), is close to zero. Such approach is partly justified by the results of the numerical simulations (Ma and Schunk, 1998; Singh and Leung, 1998), where two regions with different potential structure are observed, as well as by the agreement of our results presented below with experimental data.

So the boundary radius, \( r_b \), has been defined as the radius where simultaneously the potential is close to zero and the electric field abruptly drops and changes sign. Equation (2) has been solved numerically by starting from the sphere surface with the known potential and some potential first derivative. The potential first derivative on this surface was adjusted until the
radius defined above as the boundary has been found. Outside this boundary the assumed
density distribution is no longer applicable. We plot the normalized potential and the first
derivative of this potential over the normalized length, $x = r / R$, for $\chi_R = e \phi_R / kT = 1000$ and
$R/\lambda_D = 135$ in Figure 2. As can be seen from this figure, the transition region near the boundary
is very narrow and the boundary radius $r_b$ is easy to identify. The same holds true for all system
parameters used in our calculations. To verify the model, such calculations have been performed
on the set of system parameters for which experimental data are available. Table 1 compares the
results of these calculations with the data from TSS-1 (Dobrowolny et al., 1995) and TSS-1R
(Vannaroni et al., 1998) missions for very different system parameters. As can be seen, the ratio
of observed to calculated currents, $I/I_c$, shows good agreement despite large variations in
plasma density, temperature and sphere potential.

Figures 3 and 4 plot the results of these calculations along with all the data from
Dobrowolny et al. [1995] and Vannaroni et al. [1998]. Our Figure 3 reproduces Figure 2 from
the first paper (TSS-1 mission) with the results of our calculations inserted as the red dots. The
sphere potential and plasma parameters for these calculations, presented in Table 2, are taken
from their Table 1. The measured temperature is 0.1 eV. The three curves in this figure
correspond to three models of current collection: the Parker-Murphy model (P-M 1), the Alpert
model (Alpert et al., 1965) and the Parker-Murphy model modified for sweeping effects of the
velocity flow (P-M 2). Figure 4 reproduces Figure 1 from the paper of Vannaroni et al. [1998]
(TSS-1R mission). They compared their observed currents with that predicted by the Parker-
Murphy and Alpert models. Again, our results are added as red dots. As can be seen from
Figures 3 and 4, the results of our calculations are in reasonable agreement with the
measurements except for a few low-voltage cases presented in Figure 4 panel (a), where the
measured current-voltage characteristic is quite different from all other measurements. Our model predicts a current close to that of the Alpert model, which describes the current collection in an unmagnetized plasma. It should be noted that the results from the Alpert model shown in Figures 3 and 4 are obtained under the condition $e\varphi_R/kT \geq (R/\lambda_D)^{4/3}$ (Dobrowolny et al., 1995; Vannaroni et al., 1998; Alpert et al., 1965), which is not satisfied for typical plasma parameters at altitudes about 300-400km for large sphere radii. For the system parameters of Figure 4(a), $\left(\frac{e\varphi_R}{kT} (R/\lambda_D)^{4/3}\right) \leq 0.24$. According to the Alpert model, if this parameter is much less than one, the current should be constant, $I/I_o = 1.5$, so, the Alpert model is not applicable. For an electrodynamic tether drawing even few ampere, the radius must be so large as to make this parameter much smaller than 1, also rendering the Alpert model inapplicable. This is the situation that exists in the case of a grid-sphere that should have a large enough radius to collect a suitable current.

The current collected by the solid sphere contactor (equation (1)) can be estimated for different system parameters with the help of Table 3, which tabulates the magnitude of the normalized boundary radii, $r_b/R$, for the set of two dimensionless parameters, $R^2/\lambda_D^2$ and $e\varphi_R/kT$ determining the solution of equation (2). As can be seen from Table 3 the boundary radius is inversely proportional to $R^2/\lambda_D^2$, which can be approximated as $(r_b/R)^2 \propto (\lambda_D^2/R^2)^\sigma$ with an accuracy of about 20%. The exponent $\sigma$ depends on the normalized potential of the sphere surface, e.g., $\sigma = 0.12, 0.23, 0.28$ for $e\varphi_R/kT = 10^3, 5 \cdot 10^3, 10^4$ respectively.

We use this model to estimate the upper bound of the current collected by the grid-sphere.
3. Potential Interior of the Grid-Sphere

Following Stone et al. [2002], we assume that a grid-sphere is characterized by the transparency $\alpha$, equal approximately to the ratio of the part of the sphere surface without mesh to its total surface. Electrons accelerated by the grid-sphere potential penetrate inside the grid-sphere and cause impact ionization of neutrals. The secondary electrons produced by this process will be expelled quickly from the grid-sphere, but the ions will be kept inside it by the charge of the high energy incoming electrons. The grid-sphere ion content depends on the rate of ion production, recombination, and their flux through the grid-sphere surface. For an ionospheric altitude about 300km and above, recombination is slow compared to the ionization rate and can be neglected, as can be seen from a following simple estimate.

The main neutral components at this altitude are molecular nitrogen, and atomic oxygen. We can assume that the ionization cross-section due to collisions with the energetic electrons for all of these components is of the same order of magnitude. The ions of atomic oxygen have the longest lifetime at this altitude, which is determined by ion-molecular reactions of O$^+$ with nitrogen neutral molecules [Schunk and Nagy, 2000]. This lifetime is $t_o \sim 1000$ sec. Other ions, produced by collisions with fast electrons, are neutralized on a shorter timescale; so their contribution is about five times smaller and will be neglected. The number of oxygen ions produced per unit volume per second by ionization is $\sigma N_o j$, where $\sigma$ is the cross-section for impact ionization, $N_o$ is the atomic oxygen density, and $j$ is the electron flux density. In quasi-static equilibrium, the ionization and recombination processes balance, which can be written as $\sigma N_o j = n_i / t_o$, where $n_i$ is the oxygen ion density. For $\sigma = 10^{-20}$ m$^2$, $N_o = 5 \times 10^{14}$ m$^{-3}$, and thermal electron flux $j = n_e \sqrt{kT / 2\pi m}$, this leads to an oxygen ion density more than two orders
of magnitude larger than the density of the undisturbed plasma, \( n_\infty \), for particle energies \( kT \sim 0.1\,\text{eV} \), as can be seen from their ratio \( n_i/n_\infty = t_n \sigma N_o \sqrt{kT/2\pi m} \). Therefore, the role of recombination is negligible, and the ion content of the grid-sphere is determined by the balance between oxygen ion production and their flux through the grid-sphere surface.

In contrast to the ions, the density of the locally produced secondary electrons will be much smaller than the density of penetrating electrons. The secondary electron production rate inside the grid-sphere is roughly equal to the grid-sphere volume multiplied by the electron density production rate, which is approximately the same as for ions, \( \sigma N_o j \). The flux of the secondary electrons through the grid-sphere surface is \( 4\pi R^2 j_s \), where the grid-sphere radius is \( R \), and \( j_s \) is the secondary electron flux density. In equilibrium the production and losses should be equal, \( R \sigma N_o j \sim j_s \). Since the energy of the incoming electrons is defined by the grid-sphere surface potential, \( \varphi_R \), this equilibrium becomes \( R \sigma N_o \sqrt{e \varphi_R / K_s} \sim n_s / n \), where \( K_s \) and \( n_s \) are the kinetic energy and density of a secondary electrons, and \( n \) is the density of incoming electrons. The energy ratio is \( e \varphi_R / K_s \sim 20 - 50 \) for impact ionization of the oxygen atoms, if the grid-sphere surface potentials are in the range 100 - 1000V. For the grid-sphere radius \( R \sim 10m \), using \( \sigma \) and \( N_o \) from the previous estimate, \( n_s / n \) is less than 0.001 justifying our neglect of the secondary electrons in the calculations below.

To calculate the potential distribution inside the grid-sphere the electron and the ion densities are needed. The ionized neutrals have a large velocity relative to the grid-sphere compared to their thermal velocity because of the grid-sphere orbital motion. In the coordinate system that is attached to the grid-sphere, ions are born with a velocity of about 8 km/sec, giving them a transit time through the grid-sphere of about 0.1 - 1 msec for grid-sphere radii in the
range of 1-10m. Because of the large interior scale of the grid-sphere compared to the Debye length, it can be expected that in equilibrium most plasma inside the grid-sphere will be quasi-neutral, at least for large sphere radii and dense plasma. Maintaining quasi-neutrality inside the grid-sphere requires that the ions be quasi-trapped with a characteristic time that can be estimated assuming equal densities of ions and electrons penetrating the sphere. The time needed to produce an ion density $n_i \sim n_e$ with an ionization rate $\alpha N_{o,j}$ is $t_{pr} \sim n_e / \alpha N_{o,j}$, which is the characteristic time to replenish the ion population. With an electron velocity $v_e \propto \sqrt{\phi_R}$ for high grid-sphere surface potential, $\phi_R$, this time can be rewritten as $t_{pr}[\text{sec}] \sim C / \sqrt{e \phi_R / kT}$, where the constant $C$ is about 1sec for the particle parameters used above. This is also the characteristic time that the ion should be kept inside the grid-sphere to maintain plasma quasi-neutrality. Since this time is much longer than the transit time, even for high grid-sphere potentials, the newborn ion must experience multiple reflections before leaving the grid-sphere. Therefore a potential well inside the grid-sphere must exist.

The newborn ions can be described by a shifted Maxwell-Boltzmann distribution function describing particles in the presence of conservative force field,

$$f(t = 0, \vec{r}, \vec{v}) = C_0 \exp\left(-\frac{e \phi(\vec{r}_0)}{kT} - (\vec{v} - \vec{v}_s)^2\right)$$

Here $\vec{v}_s$ and $\vec{v}$ are the satellite and ion velocities normalized by $v_r = \sqrt{2kT / M}$, $M$ is the mass of the oxygen ion, and $\phi(\vec{r}_0)$ is the potential at the point where the ion is born (Figure 1). Due to multiple reflections inside the well the equilibrium distribution should be nearly isotropic in velocity space on a timescale long compared to the transit time. It means that the angle-dependent part of the distribution (3) vanishes for times longer than the transit time, which is also the time between ion “collisions” with the potential wall, leaving only the isotropic part.
This isotropic part can be found as the angle-independent term of the function (3) when expanded in spherical harmonics in configuration and velocity space, or by averaging this function over all angles. Therefore the distribution function averaged over the oscillations in the well, which randomize the momentum but conserve the energy, will depend only on the distance from the center of the grid-sphere, \( r = \| \vec{r} \| \), and the ion speed \( v = \| \vec{v} \| \). The angle-averaged part, \( f_0 \), of the initial distribution (3) is

\[
f_0(t = 0, r_0, v) = \frac{C_0}{2 \sqrt{v}} e^{-x^2/(2v^2)} \sinh(2\sqrt{v}r) \tag{4}
\]

The dependence of this distribution on \( r_0, v \) is independent of time so for times larger than the transition time, \( t_\tau \), the function is the same within a normalization constant, \( f_0(t > t_\tau, r_0, v) = cf_0(t = 0, r_0, v) \).

Equation (4) presents the velocity dependence of the ion distribution at the location \( r_0 \), where the particles are produced by ionization. At the location \( r \) the ion distribution can be found as the solution of the kinetic equation. Because the quasi-static distribution function is angle-independent in configuration as well as in velocity space, the kinetic equation reduces to

\[
\frac{v}{\partial r} \frac{\partial f}{\partial r} - \frac{e}{M} \frac{d\phi}{dr} \frac{\partial f}{\partial v} = 0.
\]

The solution of this equation depends on the ions energy integral and can be obtained from equation (4) by setting \( v \rightarrow \sqrt{v^2 + e[\phi(r) - \phi(r_0)]/kT} \), which can be checked by substituting directly into the kinetic equation.

As previously mentioned, there are two length scales in the electrostatic problem of grid-sphere interior potential calculation: the Debye length, and the size of the grid-sphere. Because the grid-sphere size is much larger than the ionospheric Debye length, it can be expected that the main part of the ion population is born in the quasi-neutral region with a potential \( \phi_0 \), or where
the potential is close to this value. Neglecting the small term with the negative power in sinh(2νν, of equation (4), the ion distribution can be written as

\[ f(r,v) = \frac{C}{u} \exp\left(-(u-v)^3\right), \quad u = \sqrt{v^2 + \Delta \chi}, \quad \Delta \chi = \frac{e}{kT} (\phi(r) - \phi_0) \]  \hspace{1cm} (5)

The constant \( C \) of this steady-state distribution can be found from the balance between ion production inside the grid-sphere and ion flux through the grid-sphere surface. Assuming that the potential drop inside the grid-sphere is small compared to the grid-sphere surface potential accelerating the electrons, and that the approximately neutral region is large, the radial dependence of the electron flux density, \( j \), can be neglected. So the balance between ion production and loss through the grid-sphere surface can be written,

\[ \frac{4}{3} \pi R^3 \alpha \sigma N_j = 4 \pi R^2 v^4_R \int f(R,v) v_n dv^3 \]  \hspace{1cm} (6)

where \( v_n \) is the ion velocity component normal to the grid-sphere surface. The calculation of ion flux density on the right-hand side of the expression (6) is presented in the Appendix, (A1) and (A2). The normalization constant, \( C \), in the ion distribution (5) can be expressed using equation (6) and the result is

\[ C = \frac{2 \alpha R j \sigma N}{3 \pi v_R^4 \Gamma(v_n, \Delta \chi_R)}, \quad \Delta \chi_R = \frac{e}{kT} (\phi_R - \phi_0) \]  \hspace{1cm} (7)

where \( \phi_R \) is the potential of the grid-sphere surface, \( \phi_0 \) is the potential at the point where the ion is produced, and \( \Gamma(v_n, \Delta \chi_R) \) is defined by equation (A2).

So the ion density can be found by integration of the distribution function (5), and (7) over the velocity \( \vec{v} \). The domain of integration in velocity space is restricted by the condition that the ion kinetic energy should be smaller then the depth of the potential well. The ion density calculations are presented in the Appendix. It is found (A5) that
\[ n(r) = 2 \left( \sqrt{\pi v_r} \right)^3 C \left[ \Psi(v_0, \Delta \chi) - \Psi(v_0, \Delta \chi_R) \right] \] 
\[ \text{(8)} \]

with the coefficient \( C \) defined by equation (7).

To calculate the density of the penetrating electrons we assume a one-dimensional acceleration inside the grid-sphere. This assumption has been used by Laframboise [1997] in the model of current collection for the region just outside the solid surface and in our model for current collection presented in Section 2. As shown above, the results from this model are in reasonable agreement with the experimental data from the TSS-1 and TSS-1R missions. We expect that the potential drop inside the grid-sphere is small compared to the grid-sphere surface potential. If the electric field near the surface inside the grid-sphere is comparable to the electric field outside it, the character of the density distribution will also remain close to the character of the density distribution outside the grid-sphere surface. It is in this inner region near the grid-sphere surface that the main part of the total inner potential drop, \( \Delta \chi_R \), takes place. Deeper inside, and farther from the surface, the change of potential is small and therefore the same will be true for the density, taking into account that the potential drop, \( \Delta \chi_R \), is small compared to the electron energy. Then the electron density into the sphere can be written,

\[ n_e = \alpha_j \sqrt{\frac{m}{2e\phi(r)}} \]
\[ \text{(9)} \]

where the potential can be expressed using \( \Delta \chi \) and \( \Delta \chi_R \) from equations (5) and (7)

\[ (e\phi(r) = e\phi_R + kT(\Delta \chi - \Delta \chi_R)) \].

Equating the ion density (8) to the electron density (9), and setting \( \Delta \chi \) equal to zero, the quasi-neutrality condition can be written

\[ \frac{4\sqrt{\pi}}{3} \alpha N_0 R \sqrt{\frac{M}{m}} \left( \frac{e\phi_R}{kT} - \Delta \chi_R \right) = \frac{\Gamma(v_0, \Delta \chi_R)}{\Psi(v_0, \Delta \chi = 0) - \Psi(v_0, \Delta \chi_R)} \]
\[ \text{(10)} \]
where the values of $\Gamma$ and $\Psi$ are defined by equations (A2) and (A5) respectively. As can be seen from this equation, the depth of the potential well, $\Delta \chi_R$, for fixed values of electron temperature and neutral particle density, depends only on the satellite velocity and the grid-sphere potential, but not on the grid-sphere transparency. The left-hand side of equation (10) is the product of two terms: the ratio of the grid-sphere size to the electron free path between ionization collisions; and a term primarily dependent on the grid-sphere potential. It was found that the well depth, $\Delta \chi_R$, is inversely proportional to the magnitude of these dimensionless parameters, so that for larger parameters the depth is smaller. This depth is of the same order of magnitude as the kinetic energy of the oxygen ion motion relative to the satellite (~5eV). For the combination of $\sigma N_o R = 6 \cdot 10^{-5}$ and grid-sphere potentials 100V and 1000V, the well depth is 5.7V and 4.9V respectively, while for $\sigma N_o R = 5 \cdot 10^{-6}$ the potential drops are 7.2V and 6.6V. If the parameter $\sigma N_o R$ changes from $6 \cdot 10^{-5}$ to $5 \cdot 10^{-6}$, for a grid-sphere potential of 500V, the well depth changes from 5.2V to 6.8V.

These magnitudes for the potential well are calculated using equation (8) for the ion density obtained with the help of the mathematical approximation (A5) discussed in the Appendix. While these results are needed for the self-consistent calculation of the potential distribution inside the grid-sphere presented below, the depth of the potential well can also be calculated using the exact ion density (A4) from the Appendix. The difference in the depth of the potential well from both calculations is less then 10%, i.e. the same order as the accuracy of the mathematical approximation used in the ion density calculations, as discussed in the Appendix.

We assumed above that in most of the grid-sphere interior, the potential is close to the potential determined by neutrality, and the electric field near the grid-sphere surface is large. If either assumption does not hold, the expressions for the ion and electron densities are not valid.
To check these assumptions and to calculate the potential distribution, $\Delta \chi$, inside the grid-sphere the Poisson equation should be solved. With the densities defined by equations (7)-(9) this equation can be presented as

$$\frac{1}{x^2} \frac{d}{dx} x^2 \frac{d \Delta \chi}{dx} = \Pi_1 \left( \frac{1}{\sqrt{\chi_R + \Delta \chi - \Delta \chi_R}} - \Pi_2 \frac{\Psi(v, \Delta \chi) - \Psi(v, \Delta \chi_R)}{\Gamma(v, \Delta \chi_R)} \right), \tag{11}$$

where the first term on the right-hand side is the electron density and $x(=r/R)$ is the radial coordinate $r$ normalized to the grid-sphere radius $R$. Fixing both the potential well depth, $\Delta \chi_R$, calculated from the quasi-neutrality condition, and the potential on the grid-sphere surface $\chi_R$, we vary the derivative at the grid-sphere surface until at some point inside the grid-sphere both the potential and its derivative become zero. Equation (11) has been solved for the grid-sphere potentials 100V, 500V, and 1000V for $\Pi_1 = 9 \cdot 10^5$, $1.5 \cdot 10^7$; and $\Pi_2 = 0.002$, 0.0243, which for a grid-sphere with radius 10m are approximately the maximum and minimum values of $\Pi_1$, $\Pi_2$ at altitudes of 300-500km and thermal energy 0.1eV. We chose a flux density $j$ roughly equal to the Parker-Murphy limit. Figure 5 plots the solution of equation (11) for the grid-sphere potential 500V and $\Pi_1$, $\Pi_2$ parameters listed above. As can be seen from this figure, the potential distribution strongly depends only on parameter $\Pi_1$, and in particular, on the electron Debye length. For denser plasma, i.e. for larger parameter $\Pi_1$, the region where the potential is close to quasi-neutral is also larger. The dependence on parameter $\Pi_2$ and, therefore, on the oxygen neutral density is slight. The same dependence on the parameters $\Pi_1$, $\Pi_2$ holds for the grid-sphere surface potentials of 100V and 1000V. Figure 6 plots the dependence of the
potential distribution on the grid-sphere surface potential, holding parameters \( \Pi_1, \Pi_2 \) fixed. As can be seen from Figures 5 and 6, even in the case where the potential changes more gradually, most of the grid-sphere interior has a potential close to neutrality. This validates the assumption above that ions are born mostly in the region where the potential is close to the potential of a quasi-neutral plasma. The extent of this region depends primarily on the parameter \( \Pi_1 \), and therefore on the plasma density. For the system parameters considered above, the density is high enough to create such a region. In this sense the plasma is dense, as has been initially assumed. The potential distribution presented by these figures is also consistent with the assumption that the potential drops near the grid-sphere surface and that the electric field in this region is strong, supporting the choice of the electron density distribution.

We calculated the depth of the potential well for system parameters such that the main ion population is produced in the region where the potential is close to quasi-neutral. This simplifies the calculation of the ion density, because the potential \( \phi(r_0) \) in distributions (3)-(5) is constant for all particles, but if this region is small this simplification fails. Because the depth of the potential well is defined by the balance between ion production and loss through the grid-sphere surface, smaller production rates deepen the potential well and shrink the quasi-neutral region. This can be seen in Figure 5, where smaller production rates correspond to smaller parameter \( \Pi_2 \) in equation (11). As can be seen from distribution (5) for the satellite velocity \( v_s = 7.31 \), a well depth of about 10V will confine practically all produced ions so reducing the ion production rate only shrinks the quasi-neutral region. Therefore as long as a quasi-neutral region exists inside the grid-sphere, the depth of the potential well will be about the same order of magnitude as found in the calculations above.
While a solid sphere contactor collects current only in the ram hemisphere, a grid-sphere collects current in both. Since the potential well inside the grid-sphere is small compared to the energy of the electrons accelerated by the grid-sphere surface potential, the electrons should be able to cross and leave the grid-sphere interior through the wake hemisphere if they do not intersect the mesh. These electrons will be attracted back by the grid-sphere potential, and may add to the collected current.

4. Region outside the Grid-Sphere and Grid-Sphere Current Collection

We now use the model developed above to estimate an upper bound for the current collected by the grid-sphere. First we return to the assumptions of solid sphere current collection presented in Section 2 and discuss to what degree they are applicable to a grid-sphere. We assumed that a positively charged sphere should reflect the incoming ions, so that the potential of the reflecting region is determined by the satellite orbital velocity. Clearly this potential should be independent of the sphere transparency and as valid for the grid-sphere as for the solid one. We did not consider the structure of this region, but assumed that the boundary of this region collects the upper-limit current in magnetized plasma, calculated according to Laframboise and Parker [1973]. This is still consistent with our goal of estimating the maximum collectable current. Neglecting the structure of the region where the incoming ions are reflected, we also assumed elastic reflection, and that the ion density at the inner boundary is twice the undisturbed ion density. Further, we assumed that the electron density at this boundary equals the ion density, due to the supposition that the plasma is close to neutral. These assumptions hold also for the grid-sphere, but now the electron density at the boundary will include a contribution from the flux passing through the grid-sphere. It is less clear how the grid-sphere transparency will
affect the electron density distribution that has been assumed for the region between the ion reflecting boundary and the sphere surface in equation (2) and, therefore, the radius of the current collecting boundary in equation (1). We do not think that the electron distribution will change drastically, however, for the following reasons.

As can be seen from Figures 3 and 4, the results from the Alpert model are close to the experimental data, where the model assumes a solid sphere at rest in plasma without a magnetic field. Alternatively it is known (Alpert et al., 1965) that under the same conditions, the potential distribution around a charged sphere is strongly affected by particle reflection from the body surface only if the reflection is very close to perfect, \(1 - q \ll R/l\), where \(q\) is the reflection coefficient and \(l\) is the particle free path. For the grid-sphere there also exists a flux from the sphere surface that could be considered, at least qualitatively, as the flux of reflected particles with a “reflection coefficient” roughly equivalent to the grid sphere transparency. Since the inequality above is not satisfied, we expect that the character of the potential distribution given by the Alpert model will not change dramatically if applied to a grid-sphere. Because the results of our calculations and the results of the Alpert model agree with the data for a variety of plasma densities and potentials where the condition \(e\varphi_R/kT \geq (R/\lambda_D)^{4/3}\) holds, we expect that our choice of the electron density distribution, verified for a solid sphere, is also valid for a grid-sphere. Therefore, to estimate the maximum current collected by a grid-sphere, we calculate the current collected by a solid-sphere for the same system parameters, and assume that the current collected by a grid-sphere is equal to this current times the opacity, the probability the electron collides with the mesh before leaving the interaction region. According to Section 3, electrons are one-dimensionally accelerated by the grid-sphere surface potential, but their density is approximately isotropic inside the grid-sphere. The electron penetrates inside the grid-sphere
with a probability equal to the grid-sphere transparency $\alpha$. We assume that this electron can reach either the ram or the wake hemisphere from inside the grid-sphere with equal probability, $1/2$. If the electron intersects the ram hemisphere it can escape the region of interaction with a total probability equal to the product of the probability to enter the grid-sphere, $\alpha$, the probability to reach the ram hemisphere, $1/2$, and the probability to exit through the mesh, $\alpha$, i.e. with total probability $\alpha^2/2$. This is also the probability that the electron will be found in the wake hemisphere. To estimate an upper limit for the collected current, we assume that if the electron after the first passage exits in the wake region alone it is attracted back by the grid-sphere, intersecting the grid-sphere surface two more times before finally leaving the interaction region. The probability that the electron will return from the wake region inside the grid-sphere is the product of the probability to reach the wake region, $\alpha^2/2$, calculated above, and the probability to avoid the mesh twice, $\alpha^2$, i.e. $\alpha^4/2$. As the result, an electron is able to intersect the region of interaction and escape into the surrounding plasma with the probability $\alpha^2/2 + \alpha^4/2$. So, for this scenario the collected current is

$$I_{gs} \approx \left(1 - \frac{\alpha^2}{2} - \frac{\alpha^4}{2}\right)I_{ss}$$  \hspace{1cm} (12)

Here $I_{gs}$ is the current collected by the grid-sphere, and $I_{ss}$ is the current collected by the solid sphere. The normalized current $I_{ss} / I_0$ for a solid sphere with radius 10m for typical plasma densities and particle thermal energy 0.1eV is presented in Table 4 in the two first rows. With the help of this ratio and equation (12) for the grid-sphere for a given transparency and potential, the collected current can be estimated. In Table 4 this current is presented in the two last rows in amperes where the transparency is taken to be 90%.
5. Discussion and Conclusions

In this paper we have estimated the maximum current that can be collected by a grid-sphere. This calculation takes into account the orbital grid-sphere motion and ion production inside the grid-sphere due to impact ionization by incoming electrons accelerated by the grid-sphere surface potential. These two processes lead to the formation of a small potential well inside the grid-sphere. For grid-sphere potentials of 100V and 1000V, the well depth has been found to be in the range of 5V to 7V, respectively. So the depth of this potential well is comparable to the energy of the ions born inside the sphere, which is defined by the relative velocity between the neutrals and the satellite. Such a small potential drop means that the electron motion inside the grid-sphere will be only slightly affected by this electric field. Electrons will crossover the grid-sphere interior and some fraction of uncollected electrons penetrating the ram hemisphere will leave the grid sphere through the wake hemisphere. These electrons will be attracted back by the grid-sphere potential and will additionally intersect the grid-sphere surface. So the effective opacity of the grid-sphere will be higher than that defined by the mesh transparency and a larger current can be collected.

We base this estimate of the grid-sphere current collection on the proposed model of the current collection by a solid sphere contactor. Results of the TSS-1 and TSS1R sphere contactors demonstrated that the collected currents differ significantly from that predicted by the Parker-Murphy model (Parker and Murphy, 1967) as can be seen in the Figures 3 and 4. So this model has been modified by different authors taking into account the satellite motion, ion reflection, and higher electron temperatures observed in the experiment. The results obtained by Dobrowolny et al., [1995] (Figure 3) and Laframboise [1997] with these modifications are in a good agreement with the observations of the TSS-1 mission. The curve in Figure 10 in his paper
is very close to the carve P-M 2 in Figure 3. When Laframboise [1997] compared his model with the preliminary results from the TSS-1R flight, he concluded that the model needed further modification. Good agreement with TSS-1R data has been found by Cooke and Katz [1998], but they did not discuss the currents collected by the TSS-1 mission. Data from both flights have also been compared with the prediction for the collected currents from the Alpert model (Alpert et al., 1965) for unmagnetized plasma and contactor at rest by Dobrowolny et al. [1995] and Vannaroni et al. [1998]; which agree with the measurements (Figure (3) and (4)) only if the inequality \( e\varphi_R / kT \geq (R / \lambda_p)^{4/3} \) is valid.

The main components of our model (reflection of incoming ions, potential and density distribution in this reflecting region, one-dimensional electron acceleration near the sphere surface, upper-limit for current collection in the magnetic field) have been discussed in a number of studies, in particular related to the TSS-1 and TSS-1R missions (Laframboise and Parker, 1973; Laframboise and Sonmor, 1993; Dobrowolny et al., 1995; Vannaroni et al., 1998; Katz et al., 1994; Laframboise, 1997; Cooke and Katz, 1998; Ma and Schunk, 1998; Singh and Leung, 1998). The modification we propose is based on the assumption that the current collecting region can be divided in two parts: an outer region collecting the upper-limit current permitted for two-dimensional electron acceleration, and an inner region where the electron density distribution is determined by one-dimensional acceleration. The boundary between these two regions is approximately defined as the point where the electric field abruptly changes. This is the element that has not been used in previous models. The approach appears to be reasonable, and the currents calculated from our model are in good agreement with the currents measured by the TSS-1 and TSS-1R missions. So, it can be hypothesized that this boundary between the two regions of disturbed plasma near a solid body, as introduced in the model, is a robust
characteristic of the process of current collection, at least for high enough (> 20V) sphere potentials.

We can use this estimate of the maximum current collected by a grid-sphere to compare the advantage of such an anode design for mass and drag reduction. The drag force, caused by collisions with neutrals, is proportional to the grid-sphere surface solid fraction multiplied by two, because of the interaction with the outer surface of the ram hemisphere and the inner surface of the wake hemisphere. So

\[ F_{gs} = 2(1 - \alpha)F_{ss} \]  

(13)

where: \( F_{gs} \) and \( F_{ss} \) are the friction forces acting on the grid-sphere and the solid sphere respectively. From equations (12) and (13) it follows that the drag per unit of collected current for a grid-sphere with a transparency of 80-95% is approximately 1.2-1.4 times smaller than for a solid sphere with the same radius, while the gain in the mass per unit current is 2.4-2.8 times. We can also compare these two anode designs at a fixed current. Since the current collected by a solid sphere depends on the sphere radius as \( I_s \propto \frac{R^2}{R^{2\sigma}} \), where \( \sigma \) is defined only by the sphere potential (Section 2), equating the currents (equation (12)) gives their radii as

\[ \frac{R_{gs}}{R_{ss}} = \left(1 - \alpha^2 \right) \frac{1}{2(\sigma-1)} \]  

(14)

The mass and drag ratios for these anodes are

\[ \frac{M_{gs}}{M_{ss}} = \left(\frac{R_{gs}}{R_{ss}}\right)^2 (1 - \alpha), \quad \frac{F_{gs}}{F_{ss}} = 2 \frac{M_{gs}}{M_{ss}} \]  

(15)

and for the range of parameters presented in Table 4 these ratios have a well expressed minimum as a function of the grid-sphere transparency \( \alpha \). For normalized grid-sphere potentials in the range \( e\varphi_R/kT = 10^3 - 10^4 \) this minimum corresponds to the range of
transparencies $\alpha = 0.9 - 0.76$, with corresponding mass ratios $M_{gs}/M_{ss} = 0.45 - 0.56$, and a drag ratio of about one. Of course the anode designs should be compared taking into account specific mission requirements, such as the needed current.
Appendix

1. The normalization constant, $C$, in the ion distribution function (5) has been calculated from equation (6). The ion flux density through the grid-sphere surface on the right-hand side of this equation in spherical coordinates in velocity space is

$$ I = \int f(R,v)\nu_s dv^3 = C \int d\phi \int_0^{\pi/2} d\theta \int_0^{\infty} v \cos \theta \frac{\partial}{\partial u} e^{-u^2} v^2 dv $$

(A1)

where $u(R) = \sqrt{v^2 + \Delta \chi_R}$, and $\Delta \chi_R = e(\phi_R - \phi_0)/kT$ is the normalized potential drop between the grid-sphere surface ($\phi_R$) and the neutral region ($\phi_0$). The result of the integration (with the change from the variable $v$ to the new variable $u(R)$) is

$$ I = \frac{\pi}{2} CT \gamma, \quad \gamma = z_+^R \exp\left(-\left(z_-^R\right)^2\right) + \sqrt{\pi} \left(z_+^R z_-^R + \frac{1}{2}\right) \left(1 + \frac{z_-^R}{\left|z_-^R\right|}\right) \text{erf}\left(\left|z_-^R\right|\right) $$

(A2)

where: $z_\pm^R = v_s \pm \Delta \chi_R$. The normalization constant $C$ (5) then can be found with the help of this expression for $I$ substituted in equation (6).

2. The ion density for the distribution function (5), (7) can be found as

$$ n(r) = 4\pi v_s^3 C \int_{0}^{\Delta \chi_r - \Delta \chi} \frac{v^2}{u} e^{-u^2} dv $$

(A3)

where: $u(r) = \sqrt{v^2 + \Delta \chi}$ and $\Delta \chi = e(\phi(r) - \phi_0)/kT$. The ions able to reach the grid-sphere surface with non-zero velocity are lost, and their contribution to the density is negligible in equilibrium because of their small production rate and transit time, as has been found in Section 3. Under these conditions the upper limit of the integral follows from energy conservation, $MV^2/2 + e\phi(r) = MV_R^2/2 + e\phi_R$. For $\Delta \chi = 0$ the result of the integration is

$$ n(r_0) = 2\left(\sqrt{\pi} v_s\right)^3 C \left(\sqrt{\pi} \left( e^{-v_s^2} - e^{-\left(\Delta \chi_r - \Delta \chi\right)} \right) + v_s \left(1 - \text{sgn}(v_s - \sqrt{\Delta \chi_R}) \text{erf}\left(v_s - \sqrt{\Delta \chi_R}\right)\right)\right) $$

(A4)
An approximate expression for the integrand in the equation (A3) has been used to obtain an analytic expression for the density, if \( \Delta \chi \) is comparable to \( \Delta \chi_R \). After a change of variable \( v \) to \( u(r) = \sqrt{v^2 + \Delta \chi} \), the integrand \( F = \sqrt{u^2 - \Delta \chi} \exp\left(-(u - v_s)^2\right) \) has been approximated by the function \( \left( u - \frac{\Delta \chi}{v_s} \right) \left( 1 - \exp\left(\frac{\Delta \chi}{u}\right)\right) \exp\left(-(u - v_s)^2\right) \), where the satellite velocity, normalized to the velocity of the oxygen ions that weakly changes in the altitude range 300-500km, has been taken to be \( v_s = 7.31 \). The potential well depth that has been found with the help of the equation (A4) in Section 3, for system parameters considered in this paper is restricted by condition \( \Delta \chi_R < 75 \). Both integrands are plotted in Figure 7 for different magnitudes of \( \Delta \chi \). As can be seen from this figure, the error of such approximation results in a difference in the areas not larger than 10\%. With this approximation the ion density is

\[
n(r) = 2\left(\sqrt{\pi}v_s\right)^3 C(\Psi(v_s, \Delta \chi) - \Psi(v_s, \Delta \chi_R))\]  

(A5)

\[
\Psi(v_s, \Delta \chi) = \left( v_s - \frac{\Delta \chi}{v_s} \right) \left( 1 + \text{sgn}(z_-) \text{erf}(\frac{z_-}{1}) \right) - \left( v_s - \frac{\Delta \chi}{v_s} - \frac{1}{2} \right) \left( 1 + \text{sgn}(z_- - 0.5) \text{erf}(\frac{z_- - 0.5}{1}) \right) e^{-z_-^2} \\
\text{and } \Psi(v_s, \Delta \chi_R) \text{ is the function } \Psi(v_s, \Delta \chi) \text{ calculated for } \Delta \chi = \Delta \chi_R.

Figure 1. Schematic of the model: the satellite moves from right to left with the velocity $\vec{v}_s$, $\vec{B}$ is the ambient magnetic field, the sphere (grid-sphere) radii is $R$, gray is the region close to neutral, $\vec{r}_0$ is an arbitrary point where an ion is produced, and $r_b$ indicates the boundary between the regions of one- and two-dimensional electron acceleration. The tether is along the normal to the plane.

Figure 2. Normalized potential distribution $\chi = e\phi(x)/kT$ (dashed line), and electric field, $-d\chi/dx$ (solid line) in the region of one-dimensional electron acceleration, $x = r/R$.
